

**ACUTE ILLNESS PROTOCOL
 UREA CYCLE DISORDERS
 THE INFANT/CHILD WITH CARBAMYLPHOSPHATE SYNTHETASE (CPS)
 DEFICIENCY**

INTRODUCTION

This protocol is for the sick infant/child who has previously been diagnosed with CPS deficiency. Hyperammonemic crises in children with urea cycle defects (UCDs) are medical emergencies and must be treated as such to avoid death or serious brain injury.

PATHOPHYSIOLOGY

Each of the five biochemical reactions within the urea cycle is associated with a known enzyme deficiency and a related clinical disorder as shown in the diagram below

Carbamyl phosphate synthetase (CPS) and ornithine transcarbamylase (OTC) are located in the mitochondria. The other UCD enzymes are cytosolic in location. The major site of complete urea cycle activity is the hepatocyte. CPS is autosomal recessive in inheritance; males and females are equally affected.

Unlike fats and carbohydrates, the body does not store protein. Excess protein is catabolized, releasing liberated nitrogen as ammonia (NH_3). This additional NH_3 cannot be metabolized by a defective urea cycle and so accumulates. In general, protein overload comes from either dietary protein intake beyond bodily requirements or secondary to catabolic processes, e.g. stresses of the newborn period, infection, dehydration etc...

Raised ammonia levels appear to be extremely toxic to the central nervous system, causing cerebral edema. It is not clear whether this is a primary effect and/or secondary to elevated glutamine (GLN) which, containing two nitrogenous moieties, functions as a temporary "repository" for ammonia. GLN thus accumulates in excessive quantities in affected untreated individuals, as does alanine (ALA) in the plasma. Amino acid abnormalities may precede hyperammonemia and the onset of symptoms.

PRESENTATION

- Lethargy
- Irritability
- Vomiting
- Ataxia
- Protein avoidance
- Developmental delay
- Failure to thrive
- Hyperammonemia
- Seizures
- Hepatomegaly
- Coma

Apart from arginase deficiency, which usually presents neurologically rather than as a hyperammonemic syndrome, the other urea cycle defects often present in the newborn period with catastrophic hyperammonemia, hepatomegaly, seizures and coma secondary to cerebral edema. Typically OTC and CPS have the most severe presentation but citrullinemia and argininosuccinic acidemia may also present with severe illness. However, all the UCD disorders may present later in life with a severe acute onset or a more chronic course.

ASSESSMENT

Assess for cardiorespiratory instability, dehydration, fever, infection or any other physical stressor (e.g. surgery), as a potential precipitant for metabolic decompensation. Assess hepatic and neurological status.

- **Blood glucose**
- **Electrolytes, CO₂ and blood gas**
- **Ammonia** (1.5 ml blood in sodium-heparin tube sent STAT to lab on ice)
- **Plasma amino acids**
- **LFTs** (AST,ALT,AlkPO₄, bilirubin)

Plasma ammonia is a direct index of toxicity, important for acute management. A level greater than 250 µg/dl (150 µmol/L), typically with the absence of metabolic acidosis (though may occur secondary to a primary respiratory alkalosis).

Plasma amino acids should be drawn first thing in the morning, calling the metabolic lab in advance for urgent samples. Glutamine acts as an ammonia buffer and reflects the direction of control of hyperammonemia. It is therefore essential that amino acids are checked daily in the acutely sick child with hyperammonemia secondary to a urea cycle defect.

TREATMENT

An infant/child at risk from a urea cycle disorder should be treated prospectively. The rationale of treatment includes –

1. Minimize protein intake.
2. Reverse or minimize catabolism.
3. Promote waste nitrogen excretion.

1. MINIMIZE/OPTIMIZE PROTEIN INTAKE

DIET SHOULD BE PLANNED IN CONJUNCTION WITH A METABOLIC DIETICIAN

For CPS deficiency,

the caloric intake on day 1 is provided by intravenous dextrose and supplemented with Intralipid to provide 120-130 kcal/kg/day. Protein intake should ideally commence after 24 hours to avoid catabolic breakdown of endogenous proteins.

Start after 24 hours at 0.6 grams/kg/day, administered as essential amino acids.

After 48 hours, 1.2 grams/kg/day should be supplied, half in the form of essential amino acids, the other half in the form of a natural protein source (i.e., regular infant formula) but, avoid elemental formulas as they are high in nitrogen content. Supplemental calories are

added from a non-nitrogenous formula with vitamins and minerals (Mead-Johnson 80056 formula, Ross formula Pro-Phree or equivalent). Water is then added to dilute to the proper concentration. Thereafter, the protein intake is increased gradually in 0.25 – 0.5 gram/kg increments per day to a maximum of 2 grams /kg/day.

Once patient stabilized, feedings established and the ammonia not fluctuating may switch to oral UCD medications.

2. REVERSE OR MINIMIZE CATABOLISM

The caloric intake for these infants should run at least 120-130 kcal/g/day. Accurate records of intake and output should be kept to monitor hydration. Infection as a potential but severe catabolic stressor should be considered early (when clinical signs are apparent) and managed vigorously. Avoid valproic acid, as it decreases urea cycle function and accentuates hyperammonemia.

3. PROMOTE WASTE NITROGEN EXCRETION

To help facilitate the excretion of waste nitrogen, the following medications are employed.

- (i) **Sodium benzoate** – conjugates with glycine to form hippuric acid which bypasses the urea cycle and is excreted in urine.
- (ii) **Sodium phenylacetate** – conjugates with glutamine to form phenylacetylglutamine which bypasses the urea cycle and is excreted in the urine.
- (iii) **Arginine** – to prevent ARG deficiency but must NOT BE used in arginase deficiency where there is already an excess of arginine.
- (iv) **Citrulline**. In CPS, enteral citrulline may pull aspartate into the cycle and increase nitrogen clearance BUT CAUTION, will further exacerbate citrullinemia and ASA in which there already is an excess of citrulline, therefore must be certain about the diagnosis prior to use.

Avoid carnitine as it has not been shown to be helpful. Although UCD infants are often low in carnitine, it is known to conjugate with sodium benzoate

If an IV is required, that solution should NOT contain sodium as plenty will be provided by the sodium benzoate and sodium phenylacetate.

MANAGEMENT OF PROGRESSIVE HYPERAMMONEMIA

If the blood ammonia is > 100 – 125 ug/dl (60-75 μmol/L), repeat the level. If confirmed:

- discontinue oral feedings and oral medication
- administer a 10% (or higher) glucose solution and Intralipid.
- administer the urea cycle medications as an IV bolus.

For CPS DEFICIENCY:

Sodium benzoate (250 mg/kg/day or 5.5g/m²)

Sodium phenylacetate (250 mg/kg/day or 5.5g/m²)

10% Arginine HCl (200 mg/kg/day)

(Surface area for the benzoate and phenylacetate should provide a more accurate dose in adolescents and adults)

Mix this in 35 cc/kg of 10% dextrose (no sodium) and run as a bolus over 90 minutes. This is then followed by the same solution administered as a 24 hour infusion.

- These infusions should begin during acute illness regardless of the amount of oral UCD medication already provided. Monitor ammonia levels every 4 hours, amino acids daily. Electrolytes, acid-base status and the anion gap should be monitored regularly. If another IV is required, that solution should not contain sodium.
- Glucose levels should be kept between 120-170 mg/dl. If necessary for control of hyperglycemia can use insulin (remains controversial) bearing in mind that wide swings in glucose levels affect brain osmolarity.
- Cerebral edema; Oncotic agents such as albumin will increase the overall nitrogen load but may in selected cases be considered. Mannitol has not been found to be helpful for edema secondary to hyperammonemia and steroids should not be used. Hyperventilation is recommended, but only under close appropriate supervision.

Potential side effects of sodium benzoate/phenylacetate regime

Increased incidence of nausea and vomiting with bolus.

Overdoses (3-5x recommended dose) can lead to symptoms reminiscent of hyperammonemia, specifically agitation, confusion and hyperventilation. Death has occurred (associated with cerebral edema, hypotension and cardiovascular collapse)

If the ammonia continues to rise >200-250 mg/dl (120-150 mmol/L)

Suggest transfer to PICU with metabolic and hemodialysis facilities and alert pediatric nephrology team. Remember placement of access lines for dialysis takes time so do not delay.

If dialysis is not immediately available, give a loading dose of sodium benzoate/phenylacetate, to slightly retard ammonia rise and in anticipation of dialysis ASAP.

If the ammonia continues to rise >300 mg/dl (175 mmol/L) **CONSIDER DIALYSIS**

Dialysis will clear ammonia at :-

170-200ml/min for ECMO based dialysis. Osmotic shifts have NOT been observed with this rapid rate of clearance. Additionally a hemofilter in the circuit will continue to remove ammonia between dialysis cycles.

10-30 ml/min hemodialysis

3-5 ml/min peritoneal dialysis (this rate will however take several days to significantly reduce the ammonia load, at a time when brain damage is related to duration of hyperammonemia toxicity)

*note that dialysis itself is associated with significant morbidity/mortality, particularly in the neonate, and decisions to consider using dialysis must balance the risk:benefit ratio for each child.

RECOVERY

As ammonia falls below 125-150mg/dl (60-75 μ mol/L) and clinical status returns to baseline

Can switch to oral medications and gradual reintroduction of diet in conjunction with the metabolic dietician as described above (in section “therapy”) . The use of oral sodium benzoate and sodium phenylbutyrate (the much less odiferous oral form of sodium phenylacetate) is determined, dependent on the patient, either on body weight or body surface area. The dose should be decided in conjunction with a metabolic physician if the patient does not have an up to date regimen.

NOTE that there may be a rebound hyperammonemia initially with the efflux of intracellular ammonia into the ‘relatively’ ammonia depleted blood. THUS it is important to continue closely monitoring ammonia levels until they remain stable in the normal range.

Proceedings of a consensus conference for the management of patients with Urea Cycle disorders. J Peds. Suppl. Vol. 138 (1), 2001

This protocol should be used **ONLY** in conjunction with metabolic consultation. For this please call or have paged the Genetics/Metabolism Fellow-on-call or, failing this, the Metabolic attending on call at your hospital or nearest pediatric tertiary care center (click on “metabolic consultation” at the top of the page to find local contact information [in the New England area]).
